Preface

We would like to thank Jeffrey Forbes, Bela Fejer, Leo McNamara, John Klobuchar and Jeffrey Baumgardner for numerous discussions and their helpful suggestions. We also wish to thank Celeste Gannon and Patricia Falcione for their help in manuscript typing and preparation. This research was supported in part by AFGL Contract F19628-81-K-0051 with Boston University. Michael Hicks produced the graphs using the RS/1 package on the Boston University Department of Astronomy VAX-11/750. Thanks also to the staff of the AFGL Computer Center for their help.

. A Semi-Empirical, Low-Latitude Ionospheric Model

1. INTRODUCTION

1.1 Background

Current empirical models of the low-latitude ionospheric F-region (Llewellyn and Bert; 1 Chiu; 2 and Rawer 3) can severely underestimate the daytime plasma density scale-height and total electron content (TEC) when compared with actual observations. As illustrated in Figure 1, the International Reference Ionosphere (IRI) described by Rawer 3 vields daytime TEC values which are 50 percent lower than observed TEC values at Manila (dip 14.5° N) in January 1982 (McNamara 4). Some improvement occurs when the Bent topside model is incorporated with the IRI bottomside models but the predicted values are still lower than observed. Substantial improvement is achieved when theoretically calculated profiles (Anderson 5) are used to predict TEC values. The reason is that vertical plasma transport by upward $E\times B$ drift produces both topside and bottomside profiles which are much broader (thicker) than Chapman-like profiles.

To calculate electron density profiles whenever they are needed, however, is prohibitively time-consuming on even the fastest computer. An alternate solution to this problem is to theoretically calculate electron density profiles as a function of latitude and local time and then generate coefficients which reproduce these profiles.

⁽Received for publication 9 October 1985)

⁽Due to the large number of references cited above, they will not be listed here. See References, page 101,)

The coefficients themselves are easily stored, quickly retrieved and form the basis for a fast, portable, semi-empirical computer code which will produce realistic low-latitude F-region electron density profiles. The results of this technique are called the Semi-empirical Low-latitude Ionospheric Model (SLIM).

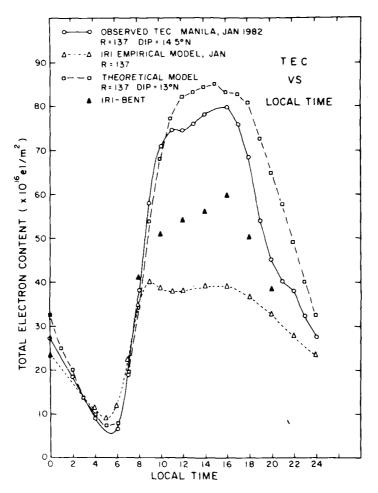

Figure 1. A Comparison Between Observed, Predicted, and Theoretically Calculated Total Electron Content (TEC) Values at Manila as a Function of Local Time for January 1982

Using the techniques described by Anderson, 5 electron densities as a function of altitude, latitude and local time are calculated by solving the time-dependent ion (0^4) continuity equation numerically. The effects of production by photosconization, loss through charge exchange with $N_{\rm o}$ and $O_{\rm o}$ and transport by diffusion,

neutral winds and vertical $\overline{E} \times \overline{B}$ drift are included. Because $\overline{E} \times \overline{B}$ drifts play such an important role in determining the electron density distribution (Hanson and Moffett and Anderson and have a seasonal and solar cycle dependence (Fejer et al 7), the calculations are carried out for equinox and solstice conditions for both solar cycle maximum and minimum periods.

Once electron density profiles are obtained, they are normalized to the peak electron density, N_{max} and appropriate coefficients which reproduce the normalized profiles (180-1800 km) every half-hour local time and every 2° dip latitude are calculated. To regenerate density profiles simply requires specifying N_{max} internally (that is, re-use of the theoretical N_{max} values) or by externally using an empirical model such as CCIR, ⁸ or observed foF2 values, and then applying the calculated coefficients applicable to the specified latitude and local time location. In the following sections, we describe briefly the various input parameters which were used in calculating theoretically the electron density profiles from the time-dependent continuity equation. The last section compares the current Chiu and Bent empirical profiles with SLIM profiles at specific latitudes and local times for equinox, solar cycle maximum conditions.

1.2 Model Calculations

The ion (0[†]) continuity equation is given by

$$\frac{\partial N_i}{\partial t} + \nabla \bullet (N_i \nabla_i) = P_i - L_i$$
 (1)

where N_i (= N_e) is the ion density; P_i , the ion production rate; L_i , the ion loss rate; and \overline{V}_i , the ion transport velocity. In the ionosphere, plasma is transported along geomagnetic field lines by diffusion and neutral winds and perpendicular to field lines primarily by $\overline{E} \times \overline{B}$ drift (Kendall and Pickering⁹). Solving Eq. (1) at low-latitudes is facilitated by transforming the independent coordinates r, θ and ϕ to a coordinate system parallel and perpendicular to \overline{B} (see Anderson⁵). Equation (1) can be written

Kendall, P.C., and Pickering, W.M. (1967) Magnetoplasma diffusion at F2-region altitudes. Planet. Space Sci., 15:825.

$$\frac{\partial N_{i}}{\partial t} + \overline{V}_{i} \bullet \overline{\nabla} N_{i} = P_{i} - L_{i} - \overline{\nabla} \bullet (N_{i} \overline{V}_{i}) - N_{i} \overline{\nabla} \bullet V_{i}$$
(2)

where \overline{V}_{i} is given by $\overline{E} \times \overline{B}/B^2$ and V_{i} includes the effects of plasma diffusion and neutral wind. The right-hand side of the equation involves terms which are second order in the coordinate parallel to \overline{B} . The left-hand side of Eq. (2) is the time rate of change of plasma density in a frame of reference which drifts with the $\overline{E} \times \overline{B}$ drift velocity. Equation (2) is solved numerically to give ion densities as a function of altitude, latitude and local time [see Moffett 10 for a review of transformations and numerical solutions].

The set of coefficients for the ion continuity equation is obtained from models of the neutral composition, ion and electron temperatures, and production, loss and diffusion rates as well as $\overline{E} \times \overline{B}$ drift and neutral wind models. Briefly, the models are the following:

- (1) The MSIS (Hedin¹¹) neutral atmospheric model is used to calculate N_2 , O_2 , and O densities and the neutral temperature, T_n , as a function of altitude, latitude and local time. An F10.7 cm flux of 180 units is chosen to represent solar cycle maximum period, and 70 units for solar minimum conditions. Average geomagnetic conditions were chosen by setting A_D = 15 in the MSIS model.
- (2) Production and diffusion rates are similar to those used by Anderson. ⁵ For the photoionization rate at the top of the atmosphere, P_{∞} , a value of $5.5 \times 10^{-7}~{\rm sec}^{-1}$ represents solar cycle maximum conditions, with a value of $2.3 \times 10^{-7}~{\rm sec}^{-1}$, for solar minimum conditions. The loss rate coefficient are adopted from Torr and Torr. ¹²
- (3) Plasma temperatures were chosen by adopting T_e/T_n and T_i/T_n ratios as a function of local time, altitude and season from the IRI model and then applying those ratios to the T_n results obtained from MSIS. Figure 2 illustrates the ratio behavior for the sunspot maximum Equinox case.

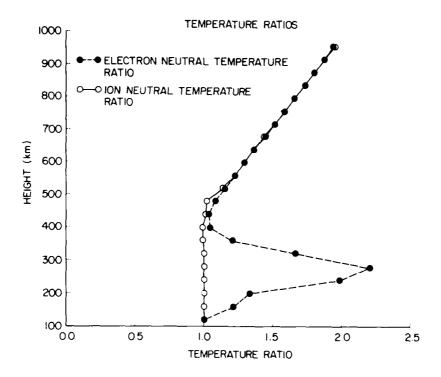

Figure 2. Ion-neutral and Electron-neutral Temperature Ratios as a Function of Altitude. The neutral temperature is adopted from the MSIS model atmosphere (see text for details)

(4) The vertical $\overline{E} \times \overline{B}$ drift velocity observed by Woodman¹³ is essential in producing and maintaining the electron density distribution observed near the magnetic equator. We adopt six vertical drift models to represent, respectively, three seasons (equinox, summer and winter solstices) at solar cycle maximum and solar cycle minimum periods. The different drift patterns are based primarily on the Jicamarca incoherent scatter radar observations reported by Fejer et al. We have assumed the vertical drift velocity is independent of altitude. The east-west component of $\overline{E} \times \overline{B}$ drift reported by Fejer et al. is neglected in the calculations because its effect on electron density profiles is negligible (Anderson 15). Figures 3a, 3b and 3c display the diurnal variation in drift for the Equinox, June solstice and December solstice cases, for solar maximum and minimum, respectively.

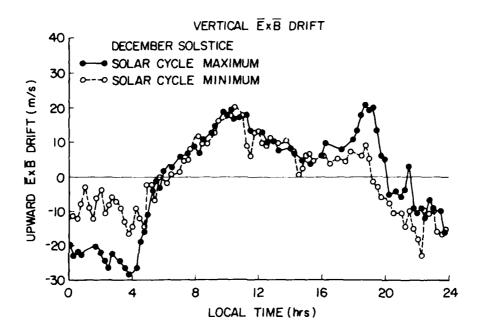

Figure 3c. Vertical $\overline{E} \times \overline{B}$ Plasma Drift as a Function of Local Time During Solar Cycle Maximum and Minimum Periods for December Solatice Conditions

- (5) The geomagnetic field is represented by a dipole model whose axis is aligned with the earth's rotational axis. We incorporate $\overline{E} \times \overline{B}$ drift models appropriate to the American sector where the dip equator lies 12° south of the geographic equator, and thus longitude effects are not addressed at this time. Further development of the model will include a tilted dipole geomagnetic field with declination specified over the regions of interest.
- (6) A simple analytic formulation for the meridional neutral wind field is adopted which makes use of observations and theory. It is constructed on the basis of observed mean (DC), diurnal (24-hour), semidiurnal (12-hour), and terdiurnal (8-hour) harmonics at Arecibo (18°N), Millstone Hill (42°N) and St. Santin (45°), with latitude variations of amplitude and phase obtained from theoretical (numerical) simulations (Forbes ^{16, 17}). The general latitudinal pattern assumed is guided by

Forbes, J. M. (1982a) Atmospheric Tides 1. Model description and results for for the solar diurnal component, J. Geophys. Res., 87:5222.

^{17.} Forbes, J. M. (1982b) Atmospheric Tides 2. The solar and lunar semi-diurnal components, J. Geophys. Res., 87:5241.

the tidal calculations of Forbes $^{16, 17}$ and the zonal mean velocities presented by Roble et al. 18 The analytic expressions, valid only for latitudes $|\theta| \le 45^{\circ}$, are given in Table 1 for Equinox, December solstice and June solstice periods.

For solstice conditions, the diurnal component, V_{24} , is shifted 10° in latitude in the direction of the solar bulge (consistent with Forbes 16). The Roble et al 18 mean meridional winds, V_0 , during solstice are shifted downwards by about 40 m/sec so that the transequatorial amplitudes are of the order 50 m/sec and the winter hemisphere reversal occurs near Millstone Hill.

The solsticial modifications to the mean and diurnal components adequately account for the main features of the observed seasonal-latitudinal dependence of the meridional wind for our purposes. Seasonal variations in the semi-diurnal and terdiurnal components are neglected. Figures 4a, 4b, and 4c give contour plots of the overall wind model spanning the simulation region where positive values represent north-to-south winds. Finally, it should be noted that while EUV varies markedly over a solar cycle, the associated variations in ion drag suppress solar cycle variations in the tidal winds, although neutral temperatures vary considerably. Therefore, we have assumed the current wind model parameterization to be independent of solar activity.

2. THE SEMI-EMPIRICAL APPROACH

2.1 The SLIM Database

As described in Section 1.1, the theoretical model is used to produce six preliminary databases. Three of these runs are for sunspot minimum (F10.7 = 70, Ap = 15) during the June solstice, December solstice, and Equinox seasons. The remaining three are for sunspot maximum (F10.7 = 180, Ap = 15) during the same seasons. Each record of data consists of profile parameters stored for a fixed geographic (geomagnetic) point and fixed time. Each database covers 25 latitudes $(24^{\circ} \, \text{S} - 24^{\circ} \, \text{N})$, every 2° and 48 times (0000h - 2330h, every 30 min). A subset of the SLIM data set, using a more coarse resolution ($N_{_{\rm C}}(h)$ every 4° in latitude and every hour of local time) is presented in tabular format for easy access and reference (Table 2).

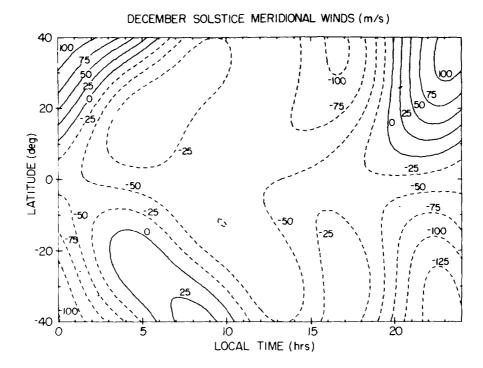

Figure 4c. Contour Plot of Meridional Neutral Wind as a Function of Latitude and Local Time for December Solstice Periods. Positive values represent north-to-south winds

The core of the SLIM approach is to identify a relatively simple $N_e(h)$ function that will have a small number of coefficients and yet provide a good representation of the profiles calculated from the theoretical model. As guiding principles, it was decided that; (1) maximum accuracy was required near the F-region peak (in both density and height), and (2) while some errors in N_e could be accepted well below or above h_{max} , the overall profile (as represented by the total electron content . (TEC) parameter) had to reproduce the theoretical results to within 5 percent or less.

The Chapman profiles developed in the earliest days of ionospheric physics offer a simple way to explain the vertical structure of plasma in the upper atmosphere. They are based on relatively simple physics and thus cannot be used to represent the entire $N_{\underline{c}}(h)$ profiles that emerge from the more sophisticated simulation techniques in use today. As simple mathematical formulas, however, they are well-suited for representing portions of the ionospheric profile. Specifically, while a

single Chapman profile cannot fit entire $N_e(h)$ profile, separate Chapman formulas can be used to reproduce the topside and bottomside components of the overall profiles with good results. it was decided, therefore, to define a "generalized" or "modified" Chapman formula with coefficients that vary for each topside and bottomside component of the $N_e(h)$ profile. The function used to fit the theoretically-lerived profiles was thus chosen to be:

$$N_{e}(h) = N_{max} \exp \left[c(1 - z - e^{-z})\right]$$

$$z = \frac{(h - h_{max})}{A}.$$
(3)

In using Eq. (3), six parameters (or coefficients) are needed to reproduce the $N_e(h)$ profile: N_{max} , h_{max} , c_{up} , A_{up} , c_{lo} , A_{lo} . The advantages of this method are: (1) the fit achieves 100 percent accuracy at N_{max} and h_{max} since they are themselves input coefficients; (2) the topside and bottomside Chapman-type functions guarantee continuity of both density and its first derivative across the fit boundary; and (3) with a fit technique weighted by density values (see below), the c's and A's chosen emphasize maximum accuracy in regions near the peak.

Included on each record of the database are two other numbers available for use and/or inspection. These are: (1) the total electron content (TEC) obtained by integrating the SLIM profile from 180 to 1800 km; and (2) 6300 \mathring{A} emission calculated from O_2^+ recombination chemistry only (and therefore, appropriate for post-sunset airglow).

2.2 Production Details

There are four steps and one version of the database is produced after each step. Initially, the theoretical model LOLAT is used to produce Database 1 (DB1). DB1 simply contains the electron density and accompanying heights. The model solves the O⁺ continuity equation, fieldline-by-fieldline, starting at the highest altitude. The order of the density and height arrays are latitude, time, and fieldline. The computer file is sequential.

Database 1 is not organized into actual electron density profiles. It is the job of program SEQDIR to sort the densities by height, time, and latitude. In addition, SEQDIR creates Database 2 (DB2) as a direct access file. A direct access file is

one in which each record of the file can be individually accessed without reading any other record. In DB2, each record contains a profile of electron densities and a height array for a particular time and latitude.

Database 2 has the disadvantage that the electron densities are given at unevenly spaced height intervals. EVEN is the program used to interpolate between the given values. The resulting profile records contain values at every 20 km from 180 to 1000 km and every 100 km from 1000 to 1800. The interpolation is done with the National Center for Atmospheric Research (NCAR) family of cubic spline interpolation, derivative and integration routines called CURV. The derivative routine is used to determine the peak electron density by identifying heights where the derivative changes sign. Arrays of the densities at these heights are scanned for the maximum value, which is identified as $N_{\rm max}$. The density profile is stored at predetermined heights so that the height array is no longer needed, making Latabase 3 (DB3) much smaller than DB2. TEC from 180 to 1800 km is also calculated using the CURV routines and included in each DB3 record.

Database 4 is the result of program CHAP fitting the profiles in DB3 to the generalized Chapman formula [Eq. (3)]. N_{max} and h_{max} are known from DB3. Combinations of values of c and A are tested until the sum of the square of the differences.

$$\sigma(e, A) = \sum_{i=1}^{n} \left\{ N_e^{Chap}(e, A, h_i) - N_e^{DB3}(h_i) \right\}^2$$

is minimized. The range of values for c and A in the first loop is

$$c = \frac{1}{16} \rightarrow 2.0$$
, $\Delta c = \frac{1}{16}$ A = 10.0 \rightarrow 200.0 km, $\Delta A = 10.0$ km.

If the minimum occurs at the endpoint of either range, the range is extended and the cycle is repeated with the same Δc and ΔA . Once an initial c and A are selected (c', A'), a new cycle is started where

$$c = (c' - \frac{1}{16}) \rightarrow (c' + \frac{1}{16}), \ \Delta c = \frac{1}{256}$$

$$A = (A' - 10.0) \rightarrow (A' + 10.0), \Delta A = 1.0$$
.

To save space, the C quoted in the SLIM tables is actually

$$C = 1000 * c$$
.

The final c and A values are added to DB4 and TEC is recalculated.

The end product is the SLIM database (DBSLIM), the ensemble of the DB4's for the six conditions of solar cycle and season.

3. COMPARISON WITH EMPIRICAL MODELS

Figure 5 compares the Semi-empirical, Low-latitude, Ionospheric Model (SLIM) with the Chiu and Bent models for Equinox, solar maximum conditions at 1400 LT. The daytime upward $\overline{E} \times \overline{B}$ drift pictured in Figure 3a causes the broad F-region profile. Respective topside scale heights at 700 km are 540 km, 150 km and 115 km. Integrating the electron density profiles with altitude give total electron contents (TEC) of 97, 48, and 61 (× 10^{12} el/cm²), respectively. The bottom portion of Figure 5 shows the comparison at 16° S dip latitude at the crest of the equatorial anomaly. Although the SLIM topside scale height is not as large as at the magnetic equator, it is still larger than those given by Chiu or Bent. In addition, the N_{max} value of 3.5×10^6 el/cm³ is significantly larger than the value at the magnetic equator due to the combination of upward and poleward $\overline{E} \times \overline{B}$ drift and downward diffusion. Note that neither the Chiu or Bent profiles show any significant change with latitude.

The most dramatic differences between SLIM and the empirical models occurs just after sunset around 2000 LT and pictured in Figure 6. At the magnetic equator (top portion), the post-sunset enhancement in upward drift lifts the F-layer to 600 km compared to $h_{\rm max}$ values of 450 km and 350 km for Bent and Chiu models, respectively. Such differences in $h_{\rm max}$ would cause significant differences in the estimated 6300 Å airglow intensity and the ion-neutral drag coefficient in the neutral momentum equation.

At 16°S dip latitude (bottom portion of Figure 6) the same upward drift causes an enhancement in N_{max} . The calculated value is 5×10^6 el/cm 3 compared with 2×10^6 el/cm 3 for Chiu and 8×10^5 el/cm 3 for the Bent model. Respective TEC values (× 10^{12} el/cm 2) are 139, 48 and 19. Finally, Figure 7 gives a comparison between SLIM, Chiu and Bent at 0500 LT. The calculated profiles at the magnetic equator and 16°S dip latitude are much more Chapman-like and in reasonable agreement with the empirical models in both N_{max} , h_{max} and topside scale height. The calculated value of TEC at 16°S dip latitude (bottom portion) is 5×10^{12} el/cm 3 which compares favorably with the Bent value of 3.5×10^{12} and a Chiu value of $9\times 10^{12}\, {\rm el/cm}^2$.

Figure 8 compares electron density profiles measured on 5 March 1969, using the Jicamarca incoherent scatter radar facility with calculated density profiles at 1400 LT and 2000 LT. The comparison demonstrates that both the large daytime plasma scale height and the calculated value of $h_{\rm max}$ at 2000 LT are in reasonable agreement with observed values. Again, it should be emphasized that the profiles are sensitive to the vertical $\overline{E} \times \overline{B}$ drift velocity whose diurnal variation may have significant day-to-day changes.

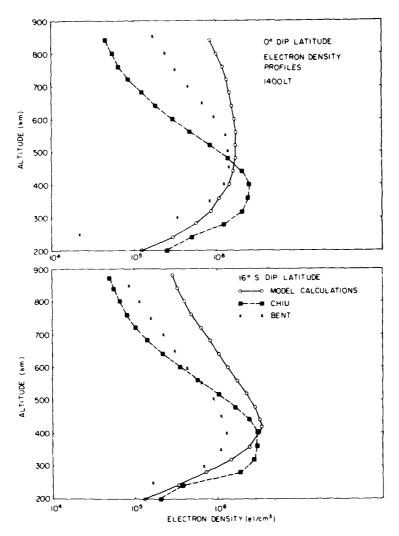

Figure 5. A Comparison Between SLIM-generated Electron Density Profiles (o—o) and the Empirical Models of Chiu (----), and Bent (xxxx) for Equinox, Solar Cycle Maximum Conditions at 1400 LT. Profiles at the magnetic equator (top portion) and at 16°S dip latitude (bottom portion)

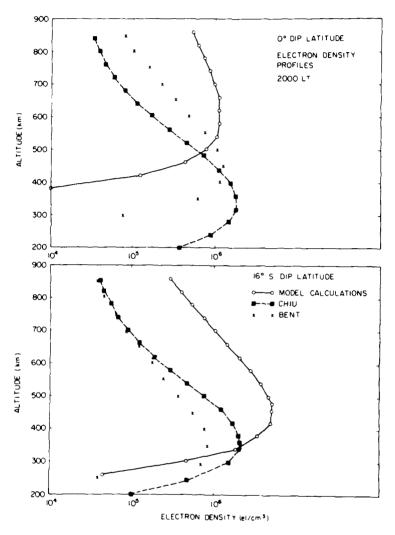

Figure 6. A Comparison Between SLIM-generated Electron Density Profiles (o——o) and the Empirical Models of Chiu (————), and Bent (xxxx) for Equinox, Solar Cycle Maximum Conditions at 2000 LT. Profiles at the magnetic equator (top portion) and at 16°S dip latitude (bottom portion)

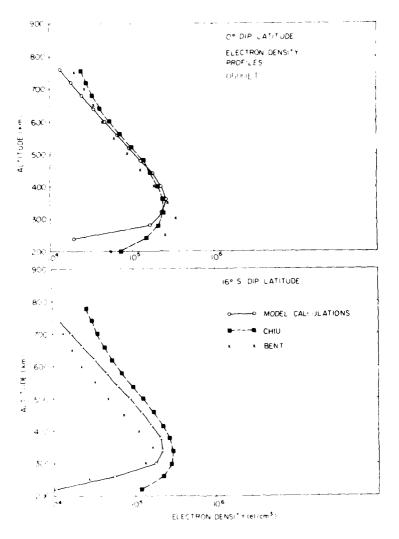

Figure 7. A Comparison Between SLIM-generated Electron Density Profiles (o——o) and the Empirical Models of Chiu (——————), and Bent (xxxx) for Equinox, Solar Cycle Maximum Conditions at 0500 LT. Profiles at the magnetic equator (top portion) and at 16°S dip latitude (bottom portion)

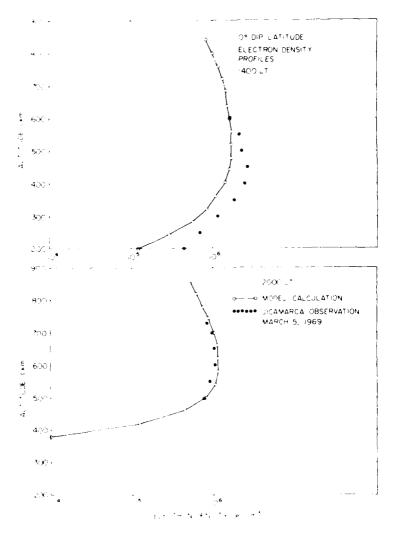

Figure 8. A Comparison Between SLIM-generated Electron Density Profiles (o——o) and Profiles Measured by the Jicamarca Incoherent Scatter Radar (••••) on 5 March 1969 at 1400 LT (top portion) and 2000 LT (bottom portion)

4. CONCLUSIONS

A very brief description of the generation of a Semi-empirical, Low-latitude, Ionospheric Model has been presented in which theoretically calculated electron density profiles are approximated by a Modified Chapman function given by Eq. (4).

$$N_e(h) = N_{max} \exp [c(1 - z - e^{-z})]$$
 (4)

where

$$z = \frac{h - h_{max}}{A}$$

and N_{max} and h_{max} represent the peak electron density and the altitude of the F2 peak, respectively. Above the peak altitude, $z_{up} = \frac{h - h_{max}}{A_{up}}$ and $c = c_{up}$ and below peak, $z_{lo} = \frac{h - h_{max}}{A_{lo}}$ and $c = c_{lo}$. The six coefficients which describe each profile are N_{max} , h_{max} , A_{up} , c_{up} , A_{lo} and c_{lo} . Appropriate coefficients which regenerate electron density profiles (180-1800 km), every half-hour local time and every 2° dip latitude between 24° N and 24° dip latitude have been calculated. Six cases have been generated, both solstice periods and one equinox period for solar cycle minimum and solar maximum conditions.

A subroutine which is able to quickly generate realistic electron density profiles has a number of applications. By providing diurnal $N_{\rm e}(h)$ and TEC values at any specified dip latitude or slant path, SLIM could be used to examine propagation effects determined by ionospheric structure. SLIM has several possible applications related to so-called "active experiments" where ambient ionospheric conditions need to be specified for pre-experiment planning and post-event analysis. In addition, such a model would yield flux-tube integrated Pedersen conductivity and electron content values which are important in determining and predicting low-latitude, instability growth rates. Finally, the program would be capable of supplying airglow intensities both in the vertical and at any slant viewing angle desired.

Table 2. Electron Density Profiles and Chapman Parameters

Each page of Table 2 provides the following values for a specified latitude, season and solar cycle:

- 1. Electron densities $(10^3/\text{cm}^3)$ from 180 to 1800 km.
- 2. $N_{\text{max}} (10^3/\text{cm}^3)$ and $h_{\text{max}} (\text{km})$.
- 3. The four Chapman parameters $\mathbf{A}_{\rm up}$ (km), $\mathbf{C}_{\rm up}$, $\mathbf{A}_{\rm lo}$ (km) and $\mathbf{C}_{\rm lo}$
- 4. Total electron content TEC (10¹²/cm²) and 630 nm O[†] recombination airglow (Rayleighs).

The above values are listed every hour local time and cover the latitude range from 24° N dip latitude (+24°) to 24° S dip latitude (-24°) in 4°-increments. The table is grouped by solar cycle (maximum and minimum) and within each solar cycle by season (Equinox, June Solstice and December Solstice). Remember that $C_{\rm up}$ = 1000 * $c_{\rm up}$ and $C_{\rm lo}$ = 1000 * $c_{\rm lo}$ where $c_{\rm up}$ and $c_{\rm lo}$ are defined by Eq. (3),
